

Introduction to Computer  
Programming Lecture 4.2:

# **Function Arguments & Scope**

Hemma Philamore

Department of Engineering Mathematics

# Passing Arguments

- Arguments allow you to pass parameters to a function (**the input**)
- The part between () **in the function definition** tells you what arguments are expected.
- We can have **multiple** arguments, separated by commas
- The **order** of the arguments is **important**
- You can **define default arguments** with the syntax **MyArgument = Value**, providing these arguments are then optional

# Passing Arguments

multiple arguments  
using commas

```
# Function to print a message
def MyFunction (MyMessage):
    print(MyMessage)
```

```
# Function to print a message or several times
def MyFunction2(MyMessage,Copies=1):
    for C in range(Copies):
        print(MyMessage)
```

Named argument:  
default value

```
# Function with more than two arguments
# arguments with default values have to come last
def MyFunction3(MyMessage,a=3, Copies=1):
    for C in range(Copies):
        print(MyMessage + " " + str(a))
```

default values  
have to come last

can use arguments  
as variables later

```
MyFunction("Hello there!")

MyFunction2("Hello there!",10)
MyFunction2("Hello there!")

MyFunction3("We will need",3,2)
MyFunction3("We will need",2)
MyFunction3("We will need",Copies=2)
```

change value  
by using  
named argument

# More Complex Arguments

```
# sums all items in a list
def SumItems(ListArg):
    Sum = 0
    for Item in ListArg:
        Sum = Sum + Item
    print(Sum)
```

goes through the list

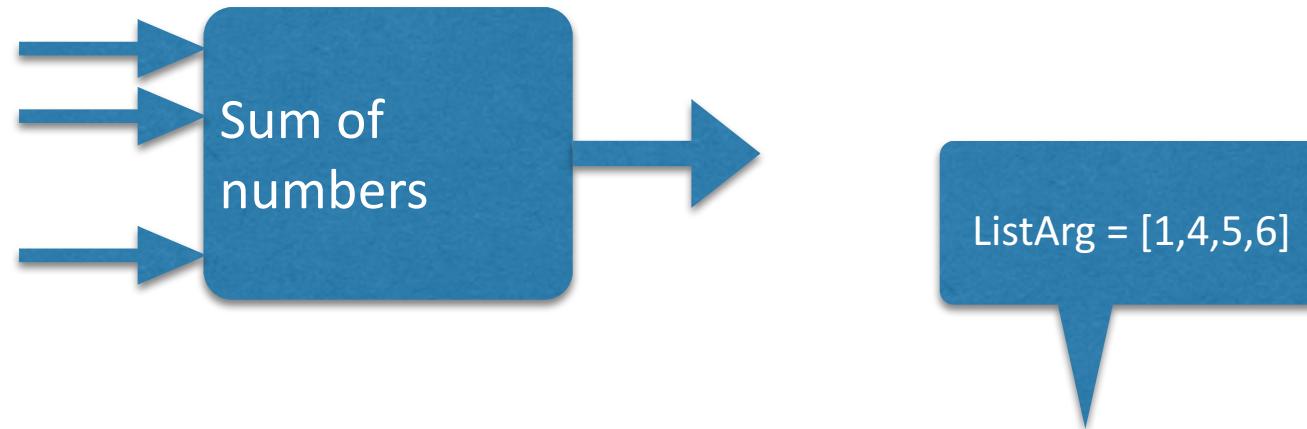

```
# list can also be of mixed types
def ShowInfo(InfoList):
    print("Name: " + InfoList[0])
    print("Age: " + str(InfoList[1]))
```

call using list

```
SumItems([1,2,3,4,5])
ShowInfo(["John Doe",23])
```

# More Complex Arguments

Sometimes we don't know the exact number of inputs

- Solution (A): Input is **one** list
- Solution (B): use the form **\*name**
  - function receives a **tuple** containing all parameters

```
def SumItems(ListArg):
```

```
def SumItems2(*Args):
```

immutable

# More Complex Arguments

```
# sums all items passed as arguments
def SumItems2(*Args):
    Sum = 0
    for Item in Args:
        Sum = Sum + Item
    print(Sum)
```

Python puts arguments  
in a tuple...

..goes through the tuple

```
SumItems2(1,2,3,4)
```

Call with multiple items

# Variable Scope

Variables **defined in** the function are **only local**!

**local** variables  
don't exist  
outside

```
def SomeFunction(number):  
    age = 25  
    name = "John"  
    .  
    .  
    .  
    return(name)
```

number = 30  
(local copy)

makes a copy  
at return statement

b = "John"

```
b = SomeFunction(30)
```

# Variable Scope

```
def PrintString():  
    MyText = "This is local"  
    print(MyText)
```

```
def PrintString2():  
    global MyText  
    print(MyText)
```

```
MyText = "GLOBAL"
```

```
PrintString()  
PrintString2()
```
